The zeta function problem

Throughout, p is a prime and $q = p^n$.

Definition

The *zeta function* of a variety *X* over \mathbb{F}_q is the series

$$\zeta_X(T) = \prod_{\substack{x \in X \text{ closed}}} (1 - T^{[\kappa(x):\mathbb{F}_q]})^{-1} = \exp\left(\sum_{n=1}^\infty \#X(\mathbb{F}_{q^n})\frac{T^n}{n}\right),$$

which represents a rational function (Dwork, Grothendieck-Artin).

For X smooth proper of dimension d, for any Weil cohomology H^i ,

$$\zeta_X(T) = \frac{P_1(T) \cdots P_{2d-1}(T)}{P_0(T) \cdots P_{2d}(T)}$$

for $P_i(T) = \det(1 - T\operatorname{Frob}_q, H^i(X))$. Also, $P_i(T) \in 1 + T\mathbb{Z}[T]$, and the \mathbb{C} -roots of $P_i(T)$ have norm $q^{-i/2}$ (Deligne).

The zeta function problem

Problem

Given a family of varieties (of fixed dimension!!), describe an efficient algorithm that, given an explicit variety X in the family, computes $\zeta_X(T)$.

In this talk, I'll only consider *X* to be a *hyperelliptic curve* of genus *g* over \mathbb{F}_q ; for p > 2, *X* always has an affine model

$$y^2 = P(x), \qquad \deg(P) \in \{2g+1, 2g+2\}.$$

Besides being the simplest family that includes all genera, these have some interest in cryptography. (Standard target: $q^g \sim 2^{160}$.)

Problem (Open unless you allow quantum computing)

Describe an algorithm to, given a hyperelliptic curve X of genus g over \mathbb{F}_q , compute $\zeta_X(T)$ in time polynomial in **all three** of $(\log p), n, g$.

Introduction

Plan for the talk

For *X* a curve of genus *g* over \mathbb{F}_q ,

$$\zeta_X(T) = \frac{P_1(T)}{(1 - T)(1 - qT)}$$

where $P_1(T) \in 1 + T\mathbb{Z}[T]$, deg $(P_1(T)) = 2g$, $P_1(T)$ has \mathbb{C} -roots of norm $q^{-1/2}$, and $P_1(T)$ is symmetric:

$$P_1(q/T) = T^{-2g}q^{-g}P_1(T).$$

I'll survey a number of techniques for computing $P_1(T)$. I'll distinguish polynomial/exponential time, but instead of finer asymptotics, I'll usually quote some sample/record CPU timings to *one* significant digit.

"sp" denotes a situation which is not entirely generic. E.g., the base field is \mathbb{F}_p for *p* a Mersenne prime, or a field admitting an optimal normal basis.

Enumeration of points

For *X* given by $y^2 = P(x)$ with *P* having no repeated roots, compute

$$\# X(\mathbb{F}_{q^{i}}) = \sum_{x \in \mathbb{P}^{1}_{\mathbb{F}_{q^{i}}}} \# \{ P \in X(\mathbb{F}_{q^{i}}) : x(P) = x \}$$

for i = 1, ..., g. Then recover $P_1(T)$ using symmetry.

Linear in q^g , so only sensible when q^g is very small.

Baby step-giant step

Shanks's algorithm for computing class groups of number fields is a *generic* group algorithm, so it can be applied to the class group of a function field, i.e., the group $J(\mathbb{F}_q)$ for *J* the Jacobian abelian variety. This helps because

 $#J(\mathbb{F}_q) = P_1(1).$

Improvements by Sutherland (generic), Matsuo-Chao-Tsujii (for curves).

Sample (K-Sutherland, 2009; 5s)

 $g = 2, p = q \sim 2^{32}.$

This is likely the best way to compute 2^{32} coefficients of the *L*-series of a genus 2 curve over \mathbb{Q} . Useless *by itself* for $g \ge 3$, but combines with ℓ -adic and *p*-adic algorithms.

イロト 不得 トイヨト イヨト 二日

Sutherland's swindle

Assume g = 2 for concreteness.

Suppose you only want $P_1(T)$ for *some* hyperelliptic curve of a given genus. Easy: find one with $\#J(\mathbb{F}_q)$ *smooth*.

Now say you want $\#J(\mathbb{F}_q)$ nearly prime. Look for a curve *X* whose quadratic twist \tilde{X} has Jacobian \tilde{J} with $\#\tilde{J}(\mathbb{F}_q)$ smooth. This helps because

$$\#\tilde{J}(\mathbb{F}_q) = P_1(-1).$$

Record (Sutherland, 2007; 34h to find one example)

 $g = 2, p = q \sim 2^{84}.$

くぼ トイヨト イヨト

Schoof's algorithm (genus 1)

For $\ell \leq 2\log q$ distinct from *p*, compute $\#X(\mathbb{F}_q) \pmod{\ell}$ by computing the action of Frobenius on the group

$$X(\overline{\mathbb{F}_q})[\ell] \cong \mathbb{F}_\ell^2$$

using division polynomials. This determines $\#X(\mathbb{F}_q)$ (and hence $P_1(T)$) in polynomial time in $\log q = n \log p$. Improvements by Elkies, Atkin; also Couveignes, Gaudry, Lercier, Mihăilescu, Morain, Schost, et al.

Record (Enge-Morain, 2006; 400d)

 $g = 1, p = q \sim 2^{8300}.$

(人間) トイヨト イヨト 二日

Schoof's algorithm (higher genus)

Pila noticed that for any *fixed* g, one can compute $P_1(T) \pmod{\ell}$ by forming a projective embedding of the Jacobian (ouch) and computing division polynomials. For g fixed, this computes $P_1(T)$ in time polynomial in $\log q$, but dependence on g is (at least) exponential.

This has only been attempted for g = 2. Improvements by Gaudry-Harley, Bernstein-Pitcher.

Record (Gaudry-Schost, 2008; 30d)

 $g = 2, p = q \sim 2^{127}$. (Sutherland's swindle is not competitive in this range.)

★ ∃ > < ∃ >

General warning

Most p-adic algorithms have at least linear dependence on p, so are not practical unless p is relatively small.

In some cases, *square root* dependence on *p* is possible. This should allow $p \le 2^{64}$.

・ 何 ト ・ ヨ ト ・ ヨ ト

Canonical lifts

Let *X* be an *ordinary* elliptic curve over \mathbb{F}_q . Then *X* has a unique lift to \mathbb{Z}_q (the unramified extension of \mathbb{Z}_p with residue field \mathbb{F}_q) preserving the endomorphism ring (Deuring; Serre-Tate).

Satoh (for $p \ge 5$; extended to p = 3 by Fouquet-Gaudry-Harley, p = 2 by Skjernaa) computes this lift using a Newton iteration involving the *p*-modular polynomial. Improvements by these authors, Taguchi, et al.

Record (Harley, 2002; 60h)

$$g = 1, q = 2^{50021}; g = 1, q = 2^{130020}$$
 (sp).

One can also handle genus 2, at least for p = 2 (using Richelot isogenies). For $g \ge 3$, the Jacobian lifts canonically *as a principally polarized abelian variety*, but not necessarily to a Jacobian.

イロト 不得 トイヨト イヨト 二日

AGM iteration

Mestre realized that for p = 2, the Newton iteration for canonical lifting induces the AGM (arithmetic-geometric mean) iteration on theta characteristics.

Record (Lercier-Lubicz, 2002; 80h)

 $g = 1, q = 2^{100002} (sp).$

This generalizes to g > 1 but is exponential in g. However...

Record (Lercier-Lubicz, 2002; 30h)

 $g = 2, q = 2^{16420}.$

A general fact

Using Dwork's proof of rationality of $\zeta_X(T)$, Lauder and Wan gave an algorithm which is polynomial time in *p*, *n*, *g*, and which generalizes vastly. Unfortunately, this is not practical.

19/26

Monsky-Washnitzer cohomology

Monsky and Washnitzer constructed an explicit *p*-adic Weil cohomology for *smooth affine* varieties, which can be described using algebraic de Rham cohomology (of a *noncanonical* lift of the curve).

Using this, Kedlaya (for $p \ge 3$; extended to p = 2 by Denef-Vercauteren) computed the Frobenius action for hyperelliptic curves.

Sample (Magma (Harrison), 2009; 60m)

 $g = 2, q = 3^{200}.$

Sample (Magma (Harrison), 2009; 60m)

g = 50, p = q = 3.

イロト 不得 トイヨト イヨト 二日

MW cohomology in medium characteristic

The previous method is at best linear in *p*. Boston-Gaudry-Schost found an algorithm for computing $P_1(T) \pmod{p}$ with *square root* dependence on *p*. Key idea: a "baby step-giant step" algorithm of Chudnovsky-Chudnovsky for solving linear recurrences with polynomial coefficients.

Harvey adapted this to compute MW cohomology with square root dependence on p. For g = 2, this beats K-Sutherland for $p \ge 2^{32}$.

Record (Harvey, 2008; 20h)

 $g = 3, p = q \sim 2^{53}.$

Record (Harvey, 2008; 40h)

$$g = 4, p = q \sim 2^{44}.$$

・ 何 ト ・ ヨ ト ・ ヨ ト

Frobenius actions on connections

Lauder suggested using deformations in *p*-adic cohomology, i.e., Picard-Fuchs equations (Gauss-Manin connections). Idea: make a pencil in which one member is "easy" and another is the desired curve. Using the easy member as an initial condition in a differential equation, compute a Frobenius action on the connection, then specialize.

Improvements by Gerkmann, Hubrechts, et al.

Sample (Magma (Hubrechts), 2009; 30m) $g = 2, q = 3^{200}.$

This method should also improve on MW cohomology for *g* large, but this requires a different implementation. (Hubrechts takes the easy curve over \mathbb{F}_p and uses MW cohomology; instead, should take a very symmetric curve for which the initial condition can be computed *exactly*.)

• • = • • = •

Other curves

Computing Frobenius on MW cohomology can be extended to superelliptic curves (Gaudry-Gürel), $C_{a,b}$ -curves (Denef-Vercauteren), nondegenerate curves (Castryck-Denef-Vercauteren, but unimplemented).

Record (Denef-Vercauteren, 2004; 8h)

$$g = 3$$
 (a $C_{3,4}$ -curve), $q = 2^{96}$.

Record (Denef-Vercauteren, 2004; 12h)

$$g = 4$$
 (a $C_{3,5}$ -curve), $q = 2^{72}$.

Using connections should be applicable even more generally. Lauder: given any fixed curve *X* over $\mathbb{Z}[1/N]$, the zeta function of $X_{\mathbb{F}_p}$ can be computed in time $O(p^{2+\varepsilon})$. (Is $O(p^{1/2+\varepsilon})$ possible?)

Higher dimension

Except for some 2-dimensional motives (Edixhoven et al.), no known way to extend ℓ -adic methods.

p-adic methods may help. MW cohomology extends with some difficulty.

Record (Abbott-K-Roe, 2005; 30h)

Quartic K3 surface, p = q = 19.

Connections should be better. Some experiments by Kloosterman (surfaces), K (threefolds).

Also possible: fibering in curves (Lauder). Applied to experiments on average rank of elliptic curves over function fields.

The end
